Taps

For simple functionality we require only one tap per N well and a single tap for the whole wafer substrate.[1] Unfortunately CMOS circuits can fail due to *Latch-up*, a condition in which the whole chip acts as a thyristor (PNPN) device in order to short Vdd to Vss.

The following (process independent) guidelines should be considered when deciding on a cell layout.

- Every well must have an appropriate tap.
- Every tap must be connected to a supply pad via unbroken metal.
- Taps should be placed as close to source connections as possible.
- Empirical rule: one tap for every 5-10 transistors.
- Layout N devices packed towards Vss and P devices packed towards Vdd.

[1] Assuming an N well process.

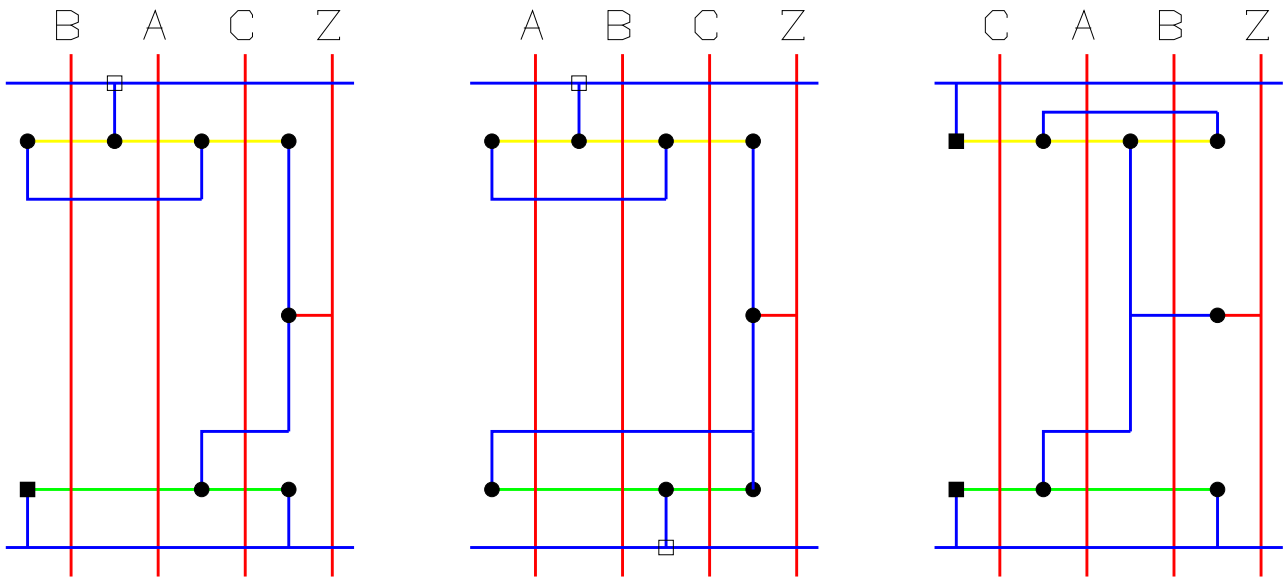
Choosing a Layout

Frequently there are several possible Euler paths for the same gate. Given that all cells must have taps, the position of the taps may effect your choice.

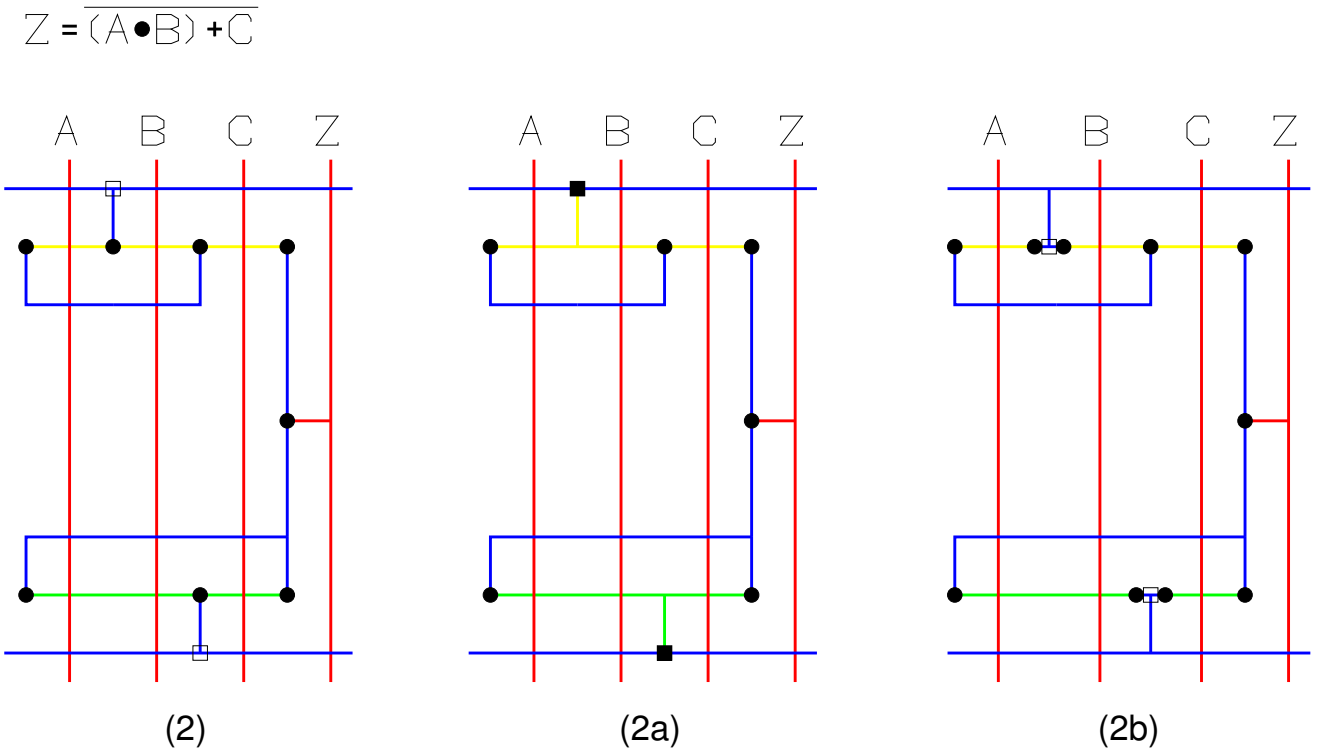
$Z = \overline{(A \bullet B) + C}$



(1) (2) (3)

Choosing a Layout

Given an identical Euler path we still have choices such as tap location.



(2) (2a) (2b)

Choosing a Layout

There is no best layout for any cell.

There are always other considerations:

- Performance:
  - Minimum source-drain capacitance.
  - Ratio of P and N device sizes.
  - Ratio of series device sizes.
- Co-existence:
  - Geometry of other cells.
  - Routing Considerations.
